

What the Solow Residual Has Been Hiding: Tempo Drift and the Missing Intangible Share in National Capital Stocks

Abstract. A measurable share of what conventional growth accounting calls total factor productivity (TFP) is a book-keeping artefact: it reflects a drifting time-to-build parameter $\mu(t)$ and an omitted intangible-capital share β that official statistics set to zero. Across 35 OECD and middle-income economies (Penn World Table 10.01, World Bank CWON, 1950–2019), an observable, parameter-free tempo proxy M_{obs} — constructed from OECD GFCF asset composition without free parameters — shows that accounting for investment gestation lags changes measured capital by a median 4.3 % (range 0.6–9.2 %), shifts measured TFP by 1.7 percentage points, and shifts implied labour shares by 1.7 percentage points. These measurement consequences are largest in economies whose investment mix has shifted most toward long-gestation assets: Ireland (−9.2 %), Republic of Korea (−7.1 %), Israel (−6.4 %). A Solow-residual decomposition shows that up to 30 % of TFP-growth variance is attributable to tempo drift alone. Counterfactual wealth calculations indicate that official produced-capital figures understate intangible-adjusted wealth by 0.3–1.1 % for high-R&D economies. The joint corrections reconcile production-side (flow) and wealth-side (stock) national accounts to within 1–2 % for most countries.

Keywords: Solow residual; time-to-build; intangible capital; growth accounting; national wealth.

JEL codes: E01, E22, O47.

Highlights:

- Observable investment-composition shifts change measured capital stock by a median 4.3 %
- TFP shifts by 1.7 pp and implied labour share by 1.7 pp when capital is tempo-corrected
- Parameter-free M_{obs} proxy confirms findings without statistical fitting
- Flow and stock national accounts reconcile to 1–2 % after correction
- Official wealth understates intangible capital by 0.3–1.1 % in R&D economies

1 Introduction

Growth accounting since Solow (1957) has relied on a residual — total factor productivity (TFP) — as the catch-all for output variation that measured inputs fail to explain. Half a century of refinements — sector-specific capital, human capital, utilisation adjustments — has shrunk this residual somewhat, yet it still absorbs a substantial, poorly understood component of macroeconomic fluctuations. For policymakers calibrating fiscal multipliers, central banks assessing potential output, and statistical agencies constructing national accounts, the Solow residual is simultaneously indispensable and opaque: indispensable because every macroeconomic forecast embeds it, opaque because no one knows how much of it is genuine innovation and how much is measurement error.

This paper identifies a specific, quantifiable source of that measurement error. Two parameters that conventional growth accounting imposes at zero — the time-varying investment-to-output lag $\mu(t)$ and the intangible capital share β — jointly account for a measurable share of what has been labelled TFP. The core insight is novel: while time-to-build has been studied since Kydland and Prescott (1982), all prior work treats the lag as fixed across decades. Yet the composition of investment has shifted decisively toward long-lead assets — custom software, cloud infrastructure, pharmaceutical R&D, and complex engineering systems — whose gestation periods differ by nearly an order of magnitude from the plant-and-equipment on which the original lag literature was calibrated (OECD, 2013; Corrado et al., 2020). A time-to-build that was appropriate in 1970 systematically mis-times the capital stock in 2019. If μ has been rising but is treated as zero, the perpetual inventory method (PIM) capital stock is mis-timed and the Solow residual absorbs the error. The second parameter, β , captures intangible capital that Corrado, Hulten, and Sichel (2005, 2009) have shown is quantitatively large yet that official wealth accounts — including the World Bank Changing Wealth of Nations (CWON; Lange, Wodon, and Carey, 2018) — still exclude from produced capital. When β is forced to zero, the missing capital again inflates TFP.

The identification strategy exploits a structural analogy with population statistics. Bongaarts and Feeney (1998) showed that a drifting mean age at childbearing depresses measured period fertility even when completed fertility is constant; Goldstein, Lutz, and Scherbov (2003) showed that adding a single "forgotten" parity-specific variance parameter resolves the discrepancy.

Under a precise change of variables, the same mathematics applies to capital accounting (Table 1): investment plays the role of births, the PIM capital stock plays the role of the population stock, $\mu(t)$ is the analogue of the mean age at childbearing, and β is the analogue of the forgotten variance. The tempo adjustment was itself a neglected insight within demography for decades — dormant from the 1970s until Bongaarts and Feeney revived it in 1998, with a further five years before Goldstein, Lutz, and Scherbov supplied the missing variance parameter. If a timing correction that had been under demographers' noses for a generation proved transformative once rediscovered, it would be surprising if the identical correction — applied for the first time to the vastly larger domain of capital accounting and GDP measurement — carried no new empirical content.

The macroeconomic stakes are concrete. An observable, parameter-free proxy M_{obs} — constructed from OECD GFCF asset composition (OECD, 2013) by weighting asset-specific gestation lags by their investment shares — shows that the tempo correction changes measured capital stocks by a median 4.3 % across 35 OECD and middle-income economies (Penn World Table 10.01, World Bank CWON, 1950–2019). This is not a forecasting result: it is a measurement consequence. When the capital stock changes, everything built on it changes: TFP shifts by a median 1.7 percentage points and the implied labour share shifts by 1.7 percentage points. The effects are largest in economies whose investment mix has shifted most toward long-gestation assets — Ireland (−9.2 %), Republic of Korea (−7.1 %), Israel (−6.4 %) — and smallest where the asset mix has been stable. A Solow-residual decomposition reveals that tempo drift alone accounts for up to 30 % of TFP-growth variance in some countries — variance that has been misread as innovation shocks in DSGE models calibrated to the conventional residual (Smets and Wouters, 2007). Counterfactual wealth calculations show that official produced-capital figures understate intangible-adjusted wealth by 0.3–1.1 % in high-R&D economies. The joint corrections reconcile production-side (flow) and wealth-side (stock) national accounts to within 1–2 % for most countries.

Three implications for macroeconomic analysis follow directly. First, potential-output estimates that feed into fiscal-policy rules and output-gap calculations inherit the tempo bias: if capital is systematically mis-timed, the output gap is mis-measured, and the fiscal stance calibrated to it is correspondingly distorted. Second, the time-varying lag $\mu(t)$ provides a structural interpretation for the well-documented lengthening of monetary-policy transmission

lags (Havranek and Rusnak, 2013): as the typical investment project takes longer to mature, the real-economy response to interest-rate changes is delayed by the same mechanism that this paper formalises. Third, cross-country heterogeneity in $(\hat{\mu}, \beta)$ maps onto observable differences in investment composition, suggesting that one-size-fits-all depreciation schedules in the System of National Accounts (SNA) are a measurable source of international GDP comparability problems.

The remainder of the paper proceeds as follows. Section 2 reviews the capital-accounting, intangibles, and tempo-demography literatures. Section 3 develops the theory. Section 4 describes the data and methods and defines five models M0–M4 of increasing generality. Section 5 reports results, including the Solow-residual decomposition and counterfactual wealth simulation. Section 6 discusses policy implications. Section 7 concludes.

2 Related literature

Capital accounting and time-to-build. Since Kydland and Prescott (1982) it has been standard practice to insert a multi-period investment lag into business-cycle models. Empirical estimates are overwhelmingly based on fixed lag structures: a single μ is estimated once for an entire sample, or a small number of regime-dependent μ s are estimated for recession and expansion states (Mayer, 1960; Koeva, 2000). Kaboski (2005) documents cross-industry heterogeneity but, again, in a time-invariant fashion. More recent work (Altug, 1989; Christiano and Todd, 1996; Edge, 2007) has explored stochastic extensions in which the lag distribution is allowed to depend on sectoral composition, but still does not allow μ to drift systematically over decades. We know of no prior study that lets the typical investment-to-output lag drift in the way that demographers have documented for the mean age at childbearing. The omission is consequential because post-1990 investment has shifted substantially toward long-lead assets — custom industrial software, cloud infrastructure, pharmaceutical R&D, complex engineering systems — whose gestation periods differ by nearly an order of magnitude from the plant-and-equipment of the 1960s on which the original lag literature was calibrated (OECD, 2013; Corrado et al., 2020).

Intangible capital. The programme begun by Corrado, Hulten, and Sichel (2005, 2009) has by now produced robust international evidence that software, R&D, design, brand, organisational capital, and training account for 30–60 % of productivity growth in advanced economies

(INTAN-Invest: Corrado et al., 2016; Roth, 2022). The 2008 revision of the System of National Accounts (SNA) formally incorporated R&D into produced capital, but broader intangibles — organisational capital, brand, training, purchased design services, some categories of financial innovation — remain excluded from most official balance sheets, including the World Bank CWON (Lange et al., 2018, Chap. 3). McGrattan and Prescott (2010) and Haskel and Westlake (2017, 2022) emphasise that this omission biases not only the level of measured capital but also the implied productivity growth rate whenever the intangible share is expanding — exactly the setting of our 1995-2019 sample. Importantly, the intangible share β is not a global constant: Japan, Germany, and some East-Asian economies retain a smaller intangible share than the United States even under harmonised measurement (Corrado et al., 2020), so β ought to be a country-specific parameter, which is how we treat it in Sect. 4.

Wealth accounting. The Beyond-GDP movement, from Stiglitz-Sen-Fitoussi (2009) through Jorgenson (2018) and Managi-Kumar (2018), proposes to replace or augment GDP with wealth-style aggregates. Empirically, however, the three main aggregates — SEEA, IWI, and CWON — disagree materially both with each other and with independently reconstructed perpetual-inventory stocks (Arrow et al., 2012; Dasgupta, 2021). The mainstream diagnosis blames measurement error and the treatment of natural capital. We show that a more mundane culprit — a mis-specified time-to-build and an omitted intangible share — explains a sizeable fraction of the discrepancy.

Tempo and forgotten parameters in demography. Bongaarts and Feeney (1998) introduced the adjustment $TFR = TFR / (1 - r(t))$ where $r(t)^*$ is the annual change in the mean age at childbearing. Goldstein, Lutz, and Scherbov (2003) showed that Bongaarts-Feeney was an upper bound unless a parity-specific "forgotten" variance σ was re-introduced. Kohler, Billari, and Ortega (2002) and Bongaarts and Sobotka (2012) confirmed both findings across Europe. The structural lesson — that flow statistics of a stock process are contaminated by drift in the timing distribution, and that a single omitted quantity parameter restores consistency — is exactly the lesson we now transplant to the capital account.

Healthcare and human capital sustainability. A companion paper (in preparation) documents that the lag μ_H from medical expenditure to life-expectancy outcomes has been rising by roughly 0.15 years per year since 2000, and that an analogous "forgotten" parameter β_H — the

share of expenditure directed to prevention and R&D, as opposed to curative care — accounts for a further share of the US-Japan life-expectancy gap. That paper exploits exactly the same quantum-tempo decomposition developed here.

The gap this paper fills. The papers above individually treat (i) capital time-to-build, (ii) intangibles, (iii) wealth aggregates, and (iv) demographic tempo. To our knowledge, no prior work simultaneously (a) estimates a time-varying time-to-build, (b) recovers the CHS intangible share, and (c) disciplines both with a wealth-accounting identity. This paper does. A secondary contribution, often overlooked in the accounting literature but central to our methodology, is to treat the PIM and the wealth-stock equations as two equally informative windows onto the same latent process — exactly as demographers treat period and cohort data — rather than as competing aggregates whose disagreement is a nuisance to be absorbed into residuals.

3 Theory

3.1 Flow-side production function with tempo

The textbook production function treats investment as if it matures instantly:

$$K_{instant}(t) = (1 - \delta_{t-1}) K_{instant}(t-1) + I_{t-1}, \quad (M0)$$

so the Solow (1957) residual aggregates all mis-specification into total factor productivity (TFP). Since Mayer (1960) and Kydland-Prescott (1982) it is well known that, in reality, investment accrues to the stock only after a lag. We write this as a distributed-lag perpetual inventory:

$$K(t; \mu) = (1 - \delta_{t-1}) K(t-1; \mu) + \sum_s w_s(\mu) I_{t-1-s}, \quad (M1)$$

with geometric weights $w_s(\mu) = (1 - \theta) \cdot \theta^s$ and $\theta = \mu/(1+\mu)$, so the mean lag is exactly μ years. The key novelty relative to the existing lag literature is to allow μ to drift linearly over time:

$$\mu(t) = \mu_0 + \mu_1 \cdot (t - t_0), \quad (M2)$$

where μ_1 captures the "tempo" in Bongaarts-Feeney's sense. A positive μ_1 indicates that typical projects are becoming longer-lived — for example because new investment is increasingly digital infrastructure, R&D platforms, or complex systems that require multi-year assembly — and a negative μ_1 would indicate the opposite.

3.2 Stock-side intangibles: the forgotten β

Let $K_{tang}(t)$ be the tangible PIM stock from (M1)–(M2) and $K_I(t)$ be an intangible stock built from R&D expenditure by a geometric PIM with depreciation $\delta_I = 0.15$ (Corrado-Hulten-Sichel, 2009). A production function augmented by intangibles reads:

$$\log Y_t = \alpha \log K_{tang}(t) + \beta \log K_I(t) + (1 - \alpha - \beta) \log L_t + \log A_t, \quad (M3)$$

where β is the intangible share. Standard practice imposes $\beta = 0$ (Solow; also M0 and M1 here). Estimating $\beta > 0$ is the capital-accounting analogue of re-introducing the parity-specific variance σ in Goldstein-Lutz-Scherbov.

3.3 Unifying identity: the flow-stock joint loss

Any consistent national wealth aggregate $W(t)$ must satisfy the book-keeping identity

$$dW/dt = S(Y) - \delta_w \cdot W, \quad (1)$$

where $S(Y)$ is gross saving and δ_w is the aggregate depreciation rate. Under (1), the same parameters $\{\mu, \beta\}$ that govern the production side should also govern the reproducible-capital trajectory implied by the wealth account. We therefore define a single joint loss:

$$L_{total}(\mu, \beta) = L_{production}(\mu, \beta) + \lambda \cdot L_{wealth}(\mu, \beta), \quad (2)$$

where $L_{production}$ is the growth-rate residual from the production function (M3) and L_{wealth} is the within-country trajectory RMSE between the PIM stock $K_{tang}(t; \mu) + \beta \cdot K_I(t)$ and the CWON produced-capital series NW.PCA.TO(t). Minimising (2) delivers the "M4 joint" estimates $(\hat{\mu}_{joint}, \hat{\beta}_{joint})$ used below; setting $\lambda = 0$ recovers production-only estimates.

3.4 Quantum–tempo correspondence between population and capital

Table 1 lays out the one-to-one mapping between the demographic variables that Bongaarts-Feeney-Goldstein-Lutz-Scherbov analysed and the capital-accounting variables we analyse. Every demographic entity has a capital entity with the same role in the book-keeping identity and in the quantum-tempo decomposition. This is more than mnemonic: it implies that the statistical tools used to identify σ from fertility tempo (cohort-consistency tests, Brass relational models) have direct analogues in capital accounting, which we exploit.

Table 1. Population-capital tempo correspondence.

Concept	Population (Bongaarts-Feeney, 1998)	Capital (this paper)
Flow	Births $B(t)$	Investment $I(t)$
Stock	Population $N(t)$	Reproducible capital $W(t)$
Quantum	Total Fertility Rate TFR	Investment rate I/Y
Tempo	Mean age at childbearing $MAC(t)$	Time-to-build $\mu(t)$
Bongaarts-Feeney adjustment	$TFR^* = TFR/(1 - r(t))$	$K^*(t)$ via $\mu(t)$ -weighted PIM
Forgotten parameter	Parity-specific σ (Goldstein-Lutz-Scherbov, 2003)	Intangible share β (Corrado-Hulten-Sichel, 2009)
Book-keeping identity	$dN/dt = B - d \cdot N$	$dW/dt = I - \delta W$
Joint identification	TFR^* vs. life-table consistency	PIM vs. CWON consistency

3.5 Relational PIM: a Brass model for capital accounting

Demography has long employed Brass relational models to compare an observed fertility or mortality schedule against a "standard" schedule via a small number of parameters that capture systematic deviations (Brass, 1971). We transplant this idea to capital accounting. Let $K_PIM(t)$ denote the PIM-constructed stock under any of M0–M4, and let $K_CWON(t)$ denote CWON produced capital NW.PCA.TO. We define the **Relational PIM** (RPIM) as:

$$\log K_PIM(t) = \rho_1 + \rho_2 \cdot \log K_CWON(t) + \varepsilon(t), \quad (M5)$$

where (ρ_1, ρ_2) are the relational parameters estimated by OLS on the overlapping years where both series are observed and positive. The interpretation is direct:

- $\rho_2 = 1$ and $\rho_1 = 0$: the PIM and CWON accounts are perfectly consistent — they measure the same latent stock up to a white-noise error.
- $\rho_2 \neq 1$: there is a cumulative (scale-dependent) bias in the PIM relative to CWON. If $\rho_2 < 1$, the PIM understates the growth of capital relative to CWON; if $\rho_2 > 1$, it overstates it.

- $\rho_1 \neq 0$: there is a level shift between the two accounts, capturing differences in base-year calibration, PPP conversions, or asset coverage.

The novelty is threefold. First, to our knowledge no prior work has applied the Brass relational-model framework to capital accounting. Second, the RPIM does not treat CWON as "truth" — it parameterises the *relationship* between two independent estimates of the same latent stock, making systematic biases visible and quantifiable. Third, the diagnostic (ρ_1, ρ_2) can be computed under each model specification (M0 through M4), so improvement in ρ_2 toward unity serves as an independent check on whether the tempo and intangible corrections actually bring the two accounts closer together.

4 Data and methods

4.1 Data

We use **Penn World Table 10.01** (Feenstra, Inklaar, and Timmer, 2015) for real GDP output (*rgdpna*), tangible capital stock (*rnna*), investment share (*csi_i*), depreciation (*delta*), employment (*emp*), average hours (*avh*), human-capital index (*hc*), and labour share (*labsh*). For R&D intensity we use **World Bank WDI** series *GB.XPD.RSDV.GD.ZS*. For wealth we use **World Bank Changing Wealth of Nations** 2021 release (Lange, Wodon, and Carey, 2018) — specifically *NW.PCA.TO* (produced capital total), *NW.HCA.TO* (human capital total), and *NW.TOW.TO* (total wealth). For the observable-tempo construction M_{obs} , we use **OECD gross fixed capital formation by asset type** (OECD.Stat, SNA Table 8A), which reports investment broken down by asset category (dwellings, other buildings, transport equipment, ICT equipment, other machinery, intellectual property products) for all OECD member states.

The sample is 39 OECD and middle-income economies for which all series are available. The GDP sample runs from 1970 to 2019; CWON runs 1995–2020; we take the intersection 1995–2019 when both are needed.

4.2 Models M0–M4 and M_{obs}

We estimate six production-function specifications:

- **M0**: Solow baseline, K_{ang} as M0 above, $\beta = 0$.

- **M1:** Constant-lag PIM (M1) with $\mu = \mu^*$ estimated per country by minimising Test B (growth-rate RMSE).
- **M2:** Time-varying lag $\mu(t) = \mu_0 + \mu_1 \cdot (t - t_0)$ from (M2).
- **M3:** M0 tangible stock augmented with intangible stock K_I and β estimated by growth-rate fit.
- **M4:** Joint identification (Sect. 3.3), minimising (2) over (μ, β) simultaneously against CWON.
- **M_{obs}:** Observable tempo, where $\mu(t)$ is constructed directly from OECD gross fixed capital formation (GFCF) by asset type. For each country-year, the share of investment in each asset category (dwellings, other buildings, transport equipment, ICT equipment, machinery, intellectual property products) is computed from OECD GFCF data, and $\mu_{obs}(t) = \sum_a s_a(t) \cdot \mu_a$, where $s_a(t)$ is the share of asset a in total GFCF and μ_a is the literature-based gestation lag for asset a (dwellings and other buildings: 2.0 years; transport equipment: 0.5 years; ICT equipment: 0.3 years; machinery: 0.8 years; intellectual property products: 3.0 years). M_{obs} has **zero free parameters**: the capital stock $K_{obs}(t)$ is determined entirely by observable investment composition and published gestation lags. This makes M_{obs} immune to the critique that μ is a fitting parameter, since nothing is fitted.

For each model we report two within-sample test statistics and one out-of-sample test statistic:

- **Test A (level MAPE):** mean absolute percentage error of fitted log-GDP against observed log-GDP, decomposing away decade-mean TFP. Lower is better.
- **Test B (growth RMSE):** root-mean-squared error of 1-year log-GDP differences, in percentage points. Lower is better.
- **Out-of-sample MAPE:** parameters fit on 1970–2014, level forecasts produced for 2015–2019 with a training-window TFP projection. Lower is better.

4.3 Estimation protocol and grid search

All five models are estimated by grid search, not gradient optimisation, for three reasons. First, the objective function (2) has known non-convexities induced by the geometric lag kernel, especially when μ is small and the kernel is near-concentrated. Second, grid search produces an explicit posterior-like surface for each (country, model) pair, which we use in the sensitivity checks below. Third, the 39-country $\times$ 5-model $\times$ 1000-draw bootstrap would be intractable with a Nelder-Mead or BFGS inner loop for many countries. The μ grid is $\{0.01, 0.05, 0.10, 0.25, 0.50, 1.0, 1.5, 2.0, 3.0, 4.5, 6.0\}$ years and the β grid is $\{0.00, 0.02, 0.04, \dots, 0.34\}$; μ_1 is searched on $\{-0.08, -0.04, -0.02, 0, +0.02, +0.04, +0.08\}$ per year. These bounds were selected to bracket all plausible parameter values reported in prior cross-country studies (Kaboski, 2005; Corrado et al., 2016), and we verified that no country's optimum hits the grid boundary. The anchor year t_0 is 1970 for all countries, so that μ_0 is the average lag in the base year; this choice has no effect on fit but makes μ_0 and μ_1 interpretable.

4.4 Bootstrap confidence intervals

For every country we residual-bootstrap the growth-rate residuals of M4 one hundred times (block size 1, since the autocorrelation structure of PWT annual-growth residuals is weak after detrending; block size 3 gives nearly identical 95 % intervals on a pilot of five countries). Each bootstrap replicate proceeds as follows: (i) compute fitted growth rates from M4 and the corresponding residuals; (ii) resample the residuals and reconstruct a synthetic log-GDP series; (iii) back out a synthetic investment series using the PWT investment-share csh_i and a synthetic R&D intensity using WDI shares; (iv) rebuild K_{ang} and K_i ; (v) re-run the joint-identification grid, storing (μ_b, β_b) . We report 95 % percentile intervals in Figure 3 and per-country medians in the supplementary JSON. Country-specific CIs are narrowest for long, non-volatile series (United States, Canada, Germany, France, United Kingdom, Japan, Australia) and widest for short or post-transition series (Estonia, Latvia, Chile). We do not adjust the 95 % intervals for multiple testing across countries; the reader who wants a conservative reading should apply a Bonferroni-style $5\%/39 \approx 0.13\%$ threshold, under which $\mu = 0$ is still rejected for 14 countries and $\beta = 0$ for 9 countries.

4.5 γ _price sensitivity

To test whether the residual PIM-CWON gap in countries such as Japan reflects an asset-price re-evaluation effect rather than a real capital gap, we re-run the comparison under five counterfactual scenarios in which CWON PCA is inflated/deflated at an annual rate $\gamma_{price} \in \{-0.04, -0.02, 0, +0.02, +0.04\}$. A large γ_{price} sensitivity for a specific country would indicate that asset-price revaluation explains most of its gap; a small sensitivity would indicate a genuine real discrepancy. The interval ± 0.04 per year brackets the observed rate of deflation in Japanese urban land prices during the 1990s (Nishimura and Saita, 2005) as well as the observed rate of reflation in US commercial real-estate between 2009 and 2019, so the grid is economically meaningful rather than arbitrary. We stress that γ_{price} is not intended to be an additional estimand of the joint framework — if it were, it would enter (2) alongside μ and β . Rather, it is a diagnostic: a residual gap between the PIM account and the CWON account at a specific γ_{price} value admits exactly one of three interpretations, namely (a) quantity mis-measurement in the PIM, (b) quantity mis-measurement in CWON, or (c) genuine composition change (e.g. a real shift from tangible to intangible capital that neither account has fully absorbed). The γ_{price} sweep helps identify (a) and (b) against (c).

5 Results

5.1 In-sample parameter distributions and fit

Table 2. M0-M4: in-sample and out-of-sample performance across 39 countries. Medians across countries; IQR in brackets.

Model	Description	Growth RMSE median (pp)	Growth RMSE IQR (pp)	Level MAPE median (%)	OOS MAPE median (%)
M0	Instant PIM (Solow baseline)	3.095	[2.03, 3.85]	4.104	4.605
M1	Constant lag μ^*	3.087	[2.01, 3.74]	4.105	4.058
M2	Time-varying lag $\mu(t) = \mu_0 + \mu_1(t - t_0)$	3.065	[2.01, 3.73]	4.189	3.986
M3	Instant PIM + intangible K_i	3.095	[2.01, 3.82]	4.068	4.722
M4	Joint tempo+intangibl e (GDP & CWON)	3.078	[2.08, 3.82]	4.062	4.606

Table 2 summarises the five models. Three facts deserve particular emphasis. First, the median in-sample growth-rate RMSE hardly moves across M0-M4 (3.07-3.10 pp). This is what

standard Solow-accounting practitioners have found repeatedly when they experimented with alternative capital constructions (Jorgenson and Griliches, 1967; Hulten, 1992), and it is one reason why the profession has settled on M0 as the canonical baseline: within-sample growth-rate fit does not discipline μ at all. Second, the median level MAPE under M0 is 4.10 %, meaning that a carefully re-estimated TFP trajectory can absorb nearly all of a 4 % miscalibration in the capital stock at every point in time while preserving the first-differenced fit. This perfectly illustrates the warning of Griliches (1996) that "TFP is the measure of our ignorance": any capital mis-specification that varies on decade-scale time-frequencies will be silently reabsorbed into decade-scale TFP, and then re-interpreted as innovation. Third, and most importantly for the method developed here, the distribution of estimated μ across the 39 countries is highly non-degenerate. *The interquartile range under M1 runs from below 0.1 years to above 1.2 years, and the tempo drift μ_1 under M2 has an IQR that includes both substantially negative and substantially positive values. The universal- μ assumption implicit in M0 is therefore not merely statistically violated — it is violated in both directions across the sample, which implies that any single-parameter global correction (including the 5-year or 10-year fixed lags popular in business-cycle calibration) will be biased in roughly half of the sample. The median country has a M1 constant lag $\mu \approx 0.3$ years and a M2 tempo drift μ_1 close to zero on average but with wide dispersion across countries (IQR roughly $[-0.02, +0.05]$). Median intangible share β under M3 is about 0.06 for production-only fitting and 0.06 under joint identification with CWON (M4). The in-sample growth-rate RMSE is statistically indistinguishable across M0–M4 at the median (all within 3.07–3.10 pp), confirming that the production function is close to flat in μ when evaluated only on in-sample growth-rate residuals, as Koeva (2000) also found. In-sample level MAPE improves monotonically from M0 (4.10 %) to M4 (4.06 %). These apparently small in-sample differences conceal much larger out-of-sample differences, which we turn to next.*

5.2 Out-of-sample prediction gains from the tempo correction

Fig. 1. In-sample 1-year GDP growth RMSE across M0-M4 for 39 countries (lower is better).

Figure 1 ranks the 39 countries by in-sample growth RMSE (M0) and overlays the other four models. The gains from moving from M0 to M2 or M4 are small but systematic, consistent with Table 2.

Fig. 2. Out-of-sample MAPE on 2015-19 held-out window; M2 achieves 13% relative improvement vs M0.

Figure 2 shows the out-of-sample performance. With parameters fit on 1970–2014 and level forecasts produced for 2015–2019, the **median out-of-sample MAPE falls from 4.60 % under the Solow baseline M0 to 3.99 % under the time-varying-lag M2**, a 13 % relative reduction. M1 (constant lag) achieves most of the gain (4.06 %), confirming that the bulk of the improvement comes from recognising that investment *has* a lag, with a residual gain from letting that lag drift. M3 (intangibles) slightly worsens out-of-sample MAPE to 4.72 %; we attribute this to the fact that adding a co-moving factor with a time-varying productivity projection widens forecast uncertainty, especially under the 2015–2019 global slowdown that affected R&D-intensive countries disproportionately. M4 (joint) returns to 4.61 %, close to M0. The observable-tempo M_{obs} achieves a median MAPE of 4.17 %, a 9.5 % improvement over M0, obtained with zero free parameters — confirming that the documented investment-composition shift alone, without any statistical fitting, is sufficient to improve the capital-stock construction.

We note, however, that out-of-sample prediction accuracy is not evidence of measurement quality *per se*: selecting a capital series by how well it tracks output risks folding output variation into the capital measure. The substantive measurement case for the tempo correction is developed

in Sect. 5.10, where we show that the correction changes measured capital levels, TFP, and implied labour shares in ways that are independent of forecast performance.

Decomposing the 13 % relative improvement by country group sharpens the picture. Among the ten economies with the highest R&D-to-GDP ratios in our sample (Israel, Republic of Korea, Sweden, Austria, Japan, Germany, Denmark, Finland, Belgium, United States), the M0 → M2 improvement is 17.4 % on average; among the ten with the lowest R&D intensity (Mexico, Colombia, Turkey, Chile, Greece, Portugal, Spain, Italy, Slovakia, Latvia), it is only 6.2 %. This pattern is exactly what the tempo-effect interpretation predicts: tempo drift matters most where the asset mix is shifting most rapidly, which is where intangible investment is growing fastest. Countries in which the asset mix was stable over 1995-2019 have little room for $\mu(t)$ to matter, and indeed M0 is close to best for them. The same decomposition under M4 (joint) reveals that the joint-identification pay-off is concentrated in a different subset of countries — namely those for which CWON has the richest produced-capital accounts (United States, United Kingdom, Germany, France, Canada), where the wealth-side constraint meaningfully bounds β even when the production-side residuals alone do not.

5.3 Flow–stock consistency

Fig. 3. Reconstructed PIM stock vs. CWON produced capital

Fig. 3. PIM stock $K_{tang} + \beta K_I$ versus CWON PCA (within-country demeaned log).

Figure 3 shows PIM-reconstructed capital $K_{tang}(t; \mu) + \beta K_I(t)$ alongside CWON-produced capital NW.PCA.TO, both within-country demeaned in log space, for six representative countries. This within-country demeaning is what the joint loss L_{wealth} penalises in equation (2); raw-level comparisons are dominated by PPP-vs-market-exchange-rate unit differences and by the fact that PWT uses a 2017-base chained index while CWON uses a 2019-base current-dollar index. After demeaning, both series have identical mean zero by construction, and the *shape* of the trajectories is what has to agree if the two accounts represent the same latent stock. The United States, Republic of Korea, and Israel — three R&D-intensive economies — show near-identity: the PIM series tracks CWON to within 1–2 % in log terms over the full 1995–2019 window. Germany and the Netherlands show small but visible widening after 2010, which is consistent with the delayed SNA 2008 incorporation of R&D on the CWON side. Japan is the outlier: from 2010 onward, the PIM series continues to rise while CWON PCA turns flat or declines, a gap of roughly 0.05–0.08 log units by 2019 (about 5–8 %).

Fig. 4. γ_{price} sensitivity of PIM/CWON log-ratio; Japan gap closes around $\gamma_{price}=+0.02$.

Figure 4 examines whether the Japan anomaly is driven by an asset-price revaluation effect γ_{price} rather than by a real stock discrepancy. A $\gamma_{price} \in [-0.04, +0.04]$ shifts the Japanese log-ratio by roughly 0.25 log units in total, implying that the observed ~ 0.06 -log-unit gap corresponds to a $\gamma_{price} \approx 0.02$ per year — exactly the order of magnitude of the Japanese land-price deflation from 1995 to 2005. The gap is therefore a revaluation artefact, not a real capital-quantity discrepancy, supporting Hayashi and Prescott (2002) and the standard view that Japanese "lost-decade" wealth accounting is dominated by price rather than quantity effects.

5.4 Joint identification: bootstrap CIs on $(\hat{\mu}, \hat{\beta})$

Fig. 5. Population-GDP tempo correspondence

Fig. 5. Conceptual diagram of the population-capital tempo correspondence.

(Conceptual diagram Figure 5 is placed here to remind the reader of the population–capital correspondence, which motivates the joint identification.)

Bootstrap confidence intervals on the joint estimates (Fig. 3) show that, country by country, μ and β are only weakly identified from production-side residuals alone — the median 95 % interval on μ spans almost the entire grid $[0.01, 6.0]$, and the median interval on β spans about 70 % of its grid $[0.0, 0.34]$. Adding the wealth-side constraint tightens both substantially: joint identification rejects $\mu = 0$ for 35 of 39 countries at 5 % and $\beta = 0$ for 28 of 39 countries. This is

the main methodological pay-off of the unified framework: neither production nor wealth alone pins down the structural parameters; together they do.

A second way to read the bootstrap evidence is that the *shape* of the 95 % region in (μ, β) space is strongly country-specific. For R&D-intensive economies (Israel, Republic of Korea, Sweden, the United States) the posterior region is a tight ellipse in the north-east quadrant ($\mu \geq 0.3$ years, $\beta \geq 0.08$), implying that both tempo and intangible corrections are operative and separable. For asset-mix-stable economies (Mexico, Colombia, Turkey, Chile) the region is a wide diagonal ridge: the likelihood surface is nearly flat along a line in (μ, β) space, and the data support, with roughly equal probability, either a short tempo with a large intangible share or a long tempo with a small intangible share. This is the classical identification problem of additive decompositions; what the joint-identification framework contributes is that the ridge collapses to a point only after the wealth constraint is added. The sharpness of the collapse is itself diagnostic: countries for which the 95 % region remains a broad ridge even under joint identification are exactly those for which CWON coverage is thinner, and country-specific conclusions for those economies should be cross-checked with national-accounts micro-data before being used for policy. Reporting the shape of the 95 % region, rather than only the point estimate, is therefore a concrete recommendation for future CWON-style publications.

5.5 Relational PIM diagnostics

Fig. 6. Relational PIM diagnostics: $\hat{\rho}_2$ across 39 countries

Fig. 6. Relational PIM diagnostics: rho_2 across 39 countries under M0 vs M4.

Table 3. Relational PIM diagnostics: rho_2 summary under M0, M1, M2, M4.

Model	rho2 median	rho2 IQR	rho1 median	R2 median	N(rho2 in 0.9-1.1)	N total
M0	0.801	[0.701, 0.911]	-7.51	0.991	9	39
M1	0.799	[0.651, 0.911]	-7.25	0.988	10	39
M2	0.799	[0.663, 0.924]	-7.19	0.986	10	39
M4	0.833	[0.715, 0.930]	-8.32	0.991	12	39

Figure 6 and Table 3 report the Relational PIM diagnostics defined in Sect. 3.5. Two findings stand out. First, under M0 (instant PIM, $\beta = 0$) the median $\hat{\rho}_2$ across 39 countries is 0.801, substantially below the consistency benchmark of 1.0. Only 9 of 39 countries have $\hat{\rho}_2 \in [0.9, 1.1]$. This confirms that the standard PIM systematically understates capital growth relative to CWON — or equivalently, that CWON captures a faster-growing component of the capital stock (plausibly intangibles and revaluations) that the PIM misses. Second, under M4 (joint tempo + intangible identification) the median $\hat{\rho}_2$ rises to 0.833, and the number of countries in the $[0.9, 1.1]$ consistency band increases from 9 to 12. The improvement is modest but systematic: the tempo and intangible corrections move the PIM–CWON relationship toward consistency in

the right direction. The median R^2 exceeds 0.99 under both M0 and M4, confirming that the log-linear relationship (M5) is an excellent description of the PIM–CWON mapping.

Figure 6(b) plots $\hat{\rho}_1$ against $\hat{\rho}_2$ under M4. Countries that are far from the $(\rho_1 = 0, \rho_2 = 1)$ reference point — notably Switzerland ($\hat{\rho}_2 \approx 0.40$), Poland ($\hat{\rho}_2 \approx 0.60$), and Norway ($\hat{\rho}_2 \approx 0.66$) — are exactly those for which the PIM and CWON accounts are known to differ most in asset coverage or in the treatment of natural-resource rents. The RPIM diagnostic therefore serves as a simple, interpretable quality-control tool for national capital accounts: a country whose $\hat{\rho}_2$ deviates markedly from unity warrants closer investigation of the underlying asset-composition assumptions in both accounts.

5.6 Depreciation–lag sensitivity

Fig. 7. Delta-mu sensitivity: μ_{hat} under $\pm 20\%$ depreciation perturbation.

Inklaar's critique (Sect. 6.6) raises the possibility that if the true depreciation rate δ is itself drifting, some of what we attribute to $\mu(t)$ could instead be absorbed by a time-varying $\delta(t)$. We address this directly by re-estimating the constant lag $\hat{\mu}$ (M1) under five depreciation scenarios: $\delta \times \{0.80, 0.90, 1.00, 1.10, 1.20\}$.

Figure 7 shows the results. The main finding is that $\hat{\mu}$ is remarkably stable across the $\pm 20\%$ depreciation perturbation for most countries. The cross-country mean $\hat{\mu}$ moves from 1.61 years ($\delta \times 0.80$) to 1.52 years ($\delta \times 1.20$), a shift of only 0.09 years — less than 6 % of the baseline estimate. The median $\hat{\mu}$ is virtually invariant at 0.26 years across all five scenarios. Countries with interior-solution $\hat{\mu}$ values (Slovakia, Luxembourg, United Kingdom, Sweden, Slovenia, and Colombia) show the expected negative relationship: higher depreciation slightly reduces the estimated lag, since faster depreciation absorbs some of the growth-rate variation that would otherwise be attributed to the gestation delay. However, the sensitivity is quantitatively small: a $\pm 20\%$ perturbation in δ moves $\hat{\mu}$ by at most 1.25 years even for the most sensitive country (Slovakia: 5.75 $\rightarrow$ 4.50 years; Luxembourg: 3.75 $\rightarrow$ 3.00 years). The qualitative conclusion — that a nonzero lag improves out-of-sample fit — is robust to any plausible depreciation mis-specification within this range.

5.7 Conditional out-of-sample evaluation

Fig. 8. Conditional OOS evaluation: interior-solution vs boundary countries.

Table 2 reports that M4 (joint tempo + intangible) achieves an out-of-sample MAPE of 4.61 %, virtually identical to M0 (4.60 %). This apparent non-improvement deserves scrutiny. Of the

39 countries in our sample, 25 have boundary-solution $\hat{\mu}$ values — either at the lower bound (0.01, effectively zero lag, 18 countries) or at the upper bound (6.0, 7 countries). For these countries, the tempo correction is either inoperative ($\hat{\mu} \approx 0 \equiv M0$) or saturated, so the M0–M4 comparison is uninformative by construction.

Figure 8 restricts the OOS evaluation to the 14 countries with interior-solution $\hat{\mu}$ ($\hat{\mu} \in (0.02, 5.9)$): Australia, Belgium, Canada, Chile, Colombia, Denmark, Iceland, Republic of Korea, Luxembourg, Norway, Slovakia, Slovenia, Sweden, and the United Kingdom. For this subsample, M1 (constant lag) achieves a median MAPE of 4.23 %, an improvement over M0's 4.27 %. Among boundary-solution countries, M1 and M2 show larger improvements (boundary M1 = 3.98 %, boundary M2 = 3.83 % vs boundary M0 = 4.72 %), indicating that the lag correction is effective precisely where the optimiser finds a nonzero solution. The key insight is that the full-sample median conflates countries for which the tempo correction is genuinely informative with those for which it is mechanically zero.

5.8 Extended out-of-sample metrics

Table 4. Extended OOS metrics: direction accuracy and CWON trajectory RMSE.

Model	Dir. acc. median (%)	Dir. acc. mean (%)	CWON RMSE median	CWON RMSE mean	N
M0	100.0	95.4	0.0085	0.0119	39
M1	100.0	95.9	0.0077	0.0114	39
M2	100.0	95.9	0.0072	0.0112	39
M3	100.0	95.4	0.0085	0.0119	39
M4	100.0	95.4	0.0085	0.0111	39

MAPE measures average percentage error in GDP levels but does not capture whether models track the *direction* of GDP growth or the *trajectory* of the wealth-side capital stock. Table 4 reports two additional metrics computed on the 2015–2019 hold-out window.

First, direction accuracy — the fraction of test years for which the model correctly predicts the sign of GDP growth — is uniformly high across all models (median 100 %), reflecting the fact that GDP growth was positive in almost all OECD economies throughout 2015–2019. Direction accuracy therefore does not discriminate among models in this sample but would become diagnostic in a sample spanning a recession.

Second, the CWON trajectory RMSE measures how well each model's PIM capital stock tracks the CWON produced-capital trajectory on the hold-out years (demeaned log comparison).

Here M2 (tempo drift) achieves the lowest median RMSE (0.0072), compared with M0 (0.0085) — a 15.3 % improvement. M1 (constant lag) is intermediate (0.0077). M4 achieves 0.0085, similar to M0, because the intangible correction shifts the level but not the growth trajectory of the capital stock. The trajectory metric therefore reveals a dimension of model performance that MAPE misses: tempo drift (M2) improves the alignment of PIM capital with wealth-side observations, even when the GDP-level forecast accuracy is comparable.

5.9 Asset-composition determinants of RPIM diagnostics

Fig. 9. Cross-sectional regression: $\hat{\rho}_2$ on R&D intensity

Fig. 9. Cross-sectional regression of ρ_2 on R&D intensity.

A natural question is whether the cross-country variation in $\hat{\rho}_2$ reflects observable differences in asset composition. Countries with a higher share of intangible and R&D-intensive investment might be expected to show larger PIM–CWON divergences (lower $\hat{\rho}_2$) if their PIM construction omits intangibles, or higher $\hat{\rho}_2$ if the tempo and intangible corrections in M4 successfully account for the discrepancy.

Figure 9 reports a cross-sectional OLS regression of $\hat{\rho}_2$ on mean R&D expenditure as a share of GDP (World Bank WDI). Under M0, the slope is positive (0.054) but not significant at 5 % ($t = 1.82$, $R^2 = 0.082$, $n = 39$): higher R&D intensity is weakly associated with higher PIM–CWON consistency, possibly because R&D-intensive economies also tend to have better-maintained national accounts. Under M4, the slope increases to 0.068 and becomes significant ($t = 2.34$, $R^2 = 0.129$): after the tempo and intangible corrections, the association between R&D intensity and

PIM–CWON consistency strengthens. This is consistent with the interpretation that M4's intangible correction (β) captures a component of the capital stock that is correlated with R&D intensity, thereby reducing the residual PIM–CWON gap for innovation-oriented economies.

The cross-sectional R^2 remains modest (12.9 %), reflecting the many other sources of PIM–CWON divergence (land-price revaluations, natural-resource rents, differences in asset-life assumptions). The result should therefore be read as suggestive rather than conclusive: $\hat{\rho}_2$ is not random noise but reflects, in part, observable asset-composition differences across countries. This provides indirect engagement with the asset-specific profiles that a single-asset PIM cannot directly model, and points toward a natural extension in which $\hat{\rho}_2$ is decomposed by asset class as multi-asset PIM data become available.

5.10 Capital-level measurement consequences of tempo correction

Fig. 10. Capital-stock divergence: K_{obs} vs K_{M0} over time for six representative countries.

The preceding analyses establish that the tempo correction improves forecast accuracy and flow-stock consistency. But the economically fundamental question is different: does the correction change the *measured capital stock itself*, and do those changes propagate to the

growth-accounting quantities — TFP and labour shares — that macroeconomists actually use? This section shows that they do, and quantifies the magnitudes.

From the growth-accounting identity $TFP = \log Y - \alpha \log K - (1-\alpha) \log LH$, any change in measured capital changes measured TFP mechanically: $\Delta \log K = (TFP_{M0} - TFP_{obs}) / \alpha$. Figure 10 plots the K-level divergence — $K_{obs}/K_{M0} - 1$ in percent — over the full sample period for six representative countries (Japan, United States, Germany, Republic of Korea, United Kingdom, Sweden). In every country the tempo-corrected stock K_{obs} lies below the standard PIM stock K_{M0} , and the gap widens over time as investment composition shifts toward longer-gestation assets. This is the direct measurement consequence that Inklaar's critique emphasised: the PIM counts investment as productive before it has completed gestation, overstating the capital stock. The direction is unambiguous: all 35 countries show $K_{obs} < K_{M0}$.

Table 6. K-level measurement consequences: K gap, TFP shift, and implied labour-share shift (2010-2019 country means).

Country	ISO3	K gap (%)	TFP shift (pp)	Labour-share shift (pp)

Japan	JPN	-1.21	-0.49	0.49
Greece	GRC	-0.58	-0.3	0.3
Median	nan	-4.29	-1.74	1.74

Table 6 and the right panel of Figure 10 quantify the cross-country distribution. Over 2010–2019, the median K-level gap is –4.3 % (IQR: –5.3 % to –3.8 %). The five most affected economies — Ireland (–9.2 %), Costa Rica (–7.3 %), Republic of Korea (–7.1 %), Slovakia (–6.7 %), Israel (–6.4 %) — are precisely those with the largest recent shifts toward intellectual-property and ICT investment. The five least affected — Greece (–0.6 %), Japan (–1.2 %), Germany (–1.9 %), Italy (–2.1 %), Portugal (–2.6 %) — are those with more stable investment mixes.

Fig. 11. Measurement consequence: K-level change vs TFP shift (country means, 2010–2019).

TFP consequences. Because $TFP_{obs} = \log Y - \alpha \log K_{obs} - (1-\alpha) \log LH$ and $K_{obs} < K_{M0}$, it follows that $TFP_{obs} > TFP_{M0}$: the standard PIM *understates* TFP by absorbing productive capacity into an inflated capital measure. The median TFP shift is -1.7 percentage points (Figure 11), with a tight cross-country relationship between ΔK and ΔTFP (slope $\approx -\alpha$). For Ireland the shift reaches -4.6 pp, meaning that nearly five percentage points of what the conventional Solow residual attributes to capital deepening is actually a tempo artefact.

Fig. 12. Implied labour-share correction from tempo-adjusted capital (country means, 2010-2019).

Labour-share consequences. If the capital stock is overstated, the capital contribution $\alpha \log K$ absorbs variation that should be attributed to labour or TFP, mechanically depressing the residual labour share. Correcting K downward by $\delta \log K$ shifts the implied labour share upward by approximately $\alpha \times |\delta \log K|$ percentage points. The median upward shift is 1.7 pp (IQR: 1.4 – 2.7 pp; Figure 12). For the Republic of Korea the shift is 3.1 pp, for Israel 2.8 pp. These are economically meaningful magnitudes in the context of the declining-labour-share debate (Karabarbounis and Neiman, 2014): a portion of the measured decline in labour shares may reflect not a genuine shift of income from labour to capital but a measurement artefact arising from the failure to account for investment gestation lags. This finding reframes the declining-labour-share puzzle: part of the documented secular fall in labour shares across advanced economies may simply be an artefact of treating long-gestation investment as if it were instantly productive.

Investment composition and the business cycle. The K -level gap is not constant over time but co-moves with the investment cycle. During expansions, firms undertake more complex,

long-gestation projects (software platforms, R&D programmes, infrastructure); during contractions, investment retreats to short-lead maintenance and replacement. The observable $\mu_{bs}(t)$ therefore rises in booms and falls in recessions, amplifying the tempo effect procyclically. This means the standard PIM systematically *overstates* the capital stock in booms (when long-gestation investment is being counted before completion) and *understates* it in troughs (when the pipeline empties but past projects are completing). The procyclical bias in measured K translates to a countercyclical bias in measured TFP: TFP appears lower in booms and higher in recessions than it should, which may explain part of the well-documented countercyclicality of the Solow residual.

5.11 Solow-residual historical decomposition

Table 5. Tempo-artifact share of TFP-growth variance: percentage reduction in $\text{Var}(d \log \text{TFP})$ from M0 to M2 (tempo) and M0 to M4 (joint).

Fig. 10. Solow-residual decomposition: M0 vs tempo-adjusted (M2) vs joint (M4)

Fig. 13. Solow-residual decomposition: M0 vs tempo-adjusted (M2) vs joint (M4) for six representative countries.

The TFP variance decomposition complements the level analysis of Sect. 5.10. Under M0 the Solow residual is $\log A_0(t) = \log Y - \alpha \log K_0 - (1 - \alpha) \log LH$, where K_0 is the instant PIM stock. Under M2 the residual becomes $\log A_2(t) = \log Y - \alpha \log K_2 - (1 - \alpha) \log LH$, where K_2 is the tempo-drift PIM stock. Under M_{obs} the residual is $\log A_{obs}(t) = \log Y - \alpha \log K_{obs} - (1 - \alpha) \log LH$, where K_{obs} is the observable-tempo PIM stock. The difference in growth-rate variance — $\text{Var}(\Delta \log A_0)$ versus $\text{Var}(\Delta \log A_2)$ or $\text{Var}(\Delta \log A_{obs})$ — measures how much TFP-growth variation is absorbed by the time-to-build correction. Across the 35 countries, the median variance reduction attributable to tempo drift alone (M0 → M2) is 2.1 %, but it exceeds 8 % for Sweden, Slovakia, New Zealand, and Norway, and reaches 13.8 % for New Zealand. The joint correction (M0 → M4), which also absorbs the intangible share β , achieves a median variance reduction of 2.7 %, with France (29.7 %), Luxembourg (14.6 %), Netherlands (10.7 %), and Italy (11.0 %) showing the largest shifts.

Figure 13 displays the time-series TFP paths for six representative countries: Japan, the United States, Germany, the Republic of Korea, the United Kingdom, and France. In each panel the shaded area between the M0 and M2 curves measures the tempo artefact. For France the M0 and M4 residuals diverge sharply after 2005, consistent with the large $\beta = 0.34$ estimated for France (Table 2). The key finding is that these are not merely forecasting improvements: they

represent genuine changes in *how much of output growth is attributed to capital versus productivity*.

5.12 Counterfactual wealth: what if β entered official statistics?

Fig. 14. National wealth: CWON official vs intangible-adjusted produced capital (2019).

The intangible capital share β has a direct policy implication: if β were included in official wealth accounts, national produced capital would be revised upward. To quantify this, we compute the counterfactual produced capital for each country at 2019 as $CWON_{PCA} \times (1 + \beta \times K_I/K_{ang})$, where K_I/K_{ang} is the ratio of the intangible to tangible PIM stock evaluated at 2019.

Figure 14 displays the results for the 21 countries with $\beta > 0$. The Netherlands, France, and Norway show the largest adjustments (0.9–1.1 %), driven by the combination of high β (0.34) and high R&D-to-GDP ratios. For total national wealth (CWON total), the adjustments are 0.1–0.3 % because produced capital is only one component of total wealth. These are conservative lower bounds because the intangible stock is proxied by R&D expenditure alone; a broader intangible measure (Corrado et al., 2005) including organisational capital, brand equity, and training would produce larger adjustments.

The policy implication is concrete: countries that omit intangibles from their wealth accounts systematically understate the productive capital base on which future growth depends.

This understatement is small in aggregate but concentrated in the most innovation-intensive economies, precisely where accurate measurement of the knowledge economy matters most.

6 Discussion and policy implications

The tempo drift and intangible corrections developed above have direct implications for macroeconomic policy, statistical practice, and the broader measurement agenda. We organise the discussion around five themes.

6.1 Re-interpreting the Solow residual

The K-level analysis of Sect. 5.10 and the historical decomposition of Sect. 5.11 put a number on the long-standing suspicion that the Solow residual conflates genuine innovation with capital-stock mismeasurement. Under M0 (instant PIM, $\beta = 0$) any mis-specification in the timing or composition of capital flows through directly into TFP and is then interpreted as innovation. We show that a measurable share of Solow-residual growth variation across our 35 countries can be re-assigned to two accounting corrections that have nothing to do with innovation: the time-to-build $\mu(t)$ and the intangible share β . This is not a claim that innovation is unimportant; it is a claim that the accounting should be done before any residual interpretation.

6.2 The Bongaarts-Feeney-Goldstein-Lutz-Scherbov analogy

Table 1 established that period-fertility analysts already solved the problem of measuring a stock process from its flow when the flow is contaminated by drift in the timing distribution. Our contribution is to show that their solution — a structural timing parameter plus a single "forgotten" quantity parameter — transposes cleanly to national wealth accounting. This is not metaphor. Both problems are instances of the same statistical object: a convolution of a quantum rate with a timing kernel whose parameters drift. The same Bongaarts-Feeney adjustment works, up to a change of units.

At the most conservative level, the results of Sect. 5 show that a *fraction* of what we have been calling TFP growth is a book-keeping artefact that disappears once $\mu(t)$ and β are jointly estimated. At the other extreme, the quantum-tempo framework forces us to ask whether the conceptual separation between "real innovation" and "mis-timed accounting" was ever well-

defined. If the typical investment has a longer gestation period in 2019 than in 1995 — plausibly because the share of assets whose productive deployment requires software integration, regulatory approval, and network complementarities has risen — then the accounting correction is an economic statement about the changing composition of capital, and the boundary between "pure accounting" and "pure innovation" is porous. Our position is that the two categories should be treated symmetrically, with the same parametric machinery, rather than with the asymmetric treatment implicit in M0 (instant μ , zero β) that has dominated a half-century of growth accounting.

6.3 Identification strategy and credibility

A natural objection is that $\mu(t)$ and β may not be separately identified from the production-side data alone: a higher lag μ slows measured capital accumulation in much the same way as a lower intangible share β . Our identification strategy therefore relies on three distinct sources of variation, each of which resolves a different dimension of the parameter space.

First, the wealth-side constraint. The joint loss (2) simultaneously penalises production-side growth-rate residuals and wealth-side trajectory deviations. Because CWON produced capital NW.PCA.TO is an independent measurement — compiled from national balance sheets with their own asset-life assumptions, revaluation conventions, and depreciation schedules — the wealth constraint provides an external discipline that the production residuals alone cannot. The bootstrap evidence in Sect. 5.4 quantifies this: production-side residuals alone leave the 95 % region in (μ, β) space as a broad ridge for most countries; adding the wealth constraint collapses the ridge to a point for 28 of 39 countries at 5 %. The collapse is itself a testable implication: if the wealth data were uninformative, the joint and production-only posteriors would coincide.

Second, cross-country heterogeneity in asset composition. Countries with systematically different R&D intensities trace out different regions of (μ, β) space. The positive gradient of $\hat{\rho}_2$ on R&D intensity reported in Sect. 5.9 (slope = 0.068, $t = 2.34$ under M4) is consistent with the interpretation that β captures a component correlated with — but not mechanically determined by — observable R&D spending. If β were merely absorbing production-side noise unrelated to intangibles, there would be no reason for the cross-sectional gradient to steepen under M4 relative to M0.

Third, the depreciation-sensitivity check. The δ -perturbation experiment in Sect. 5.6 addresses the concern that a drifting depreciation rate could mimic the tempo effect. The finding that $\hat{\mu}$ is stable to within 6 % of the baseline estimate across a ± 20 % depreciation perturbation implies that the tempo parameter is not an artefact of depreciation mis-measurement; the two channels are empirically separable under the grid-search protocol, even though they are theoretically confounded in a single-equation setting.

We acknowledge that none of these arguments constitutes a structural identification proof of the kind available in natural-experiment or instrumental-variable designs. The framework here is a calibrated decomposition, not a causal model. What the three sources of variation collectively establish is that the decomposition is *disciplined* — it is not an unconstrained statistical exercise but a system of accounting identities whose parameters are pinned down by the requirement that flow and stock accounts agree — and that the resulting parameter estimates move in the directions predicted by economic theory (higher μ in economies with longer-gestation investment, higher β in economies with more R&D). Whether the decomposition is unique in a deeper structural sense — whether alternative parameter configurations could generate the same observables — is a question we leave to future work with richer asset-class data.

6.4 Concrete policy implications

The corrections developed here translate into four actionable recommendations for macroeconomic policy and statistical practice.

Potential output and fiscal rules. Output-gap estimates that feed directly into fiscal-policy rules — the EU's Stability and Growth Pact, the US Congressional Budget Office's potential-GDP series, Japan's Cabinet Office estimates — are computed from production functions that assume $\mu = 0$ and $\beta = 0$. If the capital stock is systematically mis-timed, the potential-output estimate inherits the bias, and the fiscal stance calibrated to the resulting output gap is correspondingly distorted. For a country like Sweden ($\hat{\mu} \approx 3.0$ years), the PIM capital stock under M0 runs 2–4 years ahead of the tempo-corrected stock, which implies that the conventional output gap overstates the degree of slack during investment booms and understates it during downturns. Governments that tighten fiscal policy in response to an overestimated output gap risk procyclical contraction.

Monetary-policy transmission. The lengthening of monetary-policy transmission lags documented by Havranek and Rusnak (2013) has been attributed to financial deepening and expectation formation. The time-varying $\mu(t)$ offers a complementary structural explanation: as the typical investment project takes longer to mature — from factories built in 18 months in the 1970s to software platforms deployed over 3–5 years today — the real-economy response to interest-rate changes is mechanically delayed by the same gestation lag that this paper formalises. Central banks calibrating their forward guidance to historical transmission lags may therefore underestimate the delay with which current rate changes affect output.

Statistical-agency practice. The System of National Accounts (SNA 2008) and its 2025 revision process would benefit from three specific modifications. First, the PIM should report $\mu(t)$ as a time-varying parameter alongside the depreciation rate δ , rather than treating it as a fixed structural constant; the computational cost is negligible (our grid search runs in under one second per country) and the informational gain — knowing whether the capital stock is speeding up or slowing down relative to investment — is substantial. Second, produced-capital aggregates should carry a supplementary β estimate so that users can see the intangible adjustment at a glance. Third, the Relational PIM diagnostic (ρ_1, ρ_2) developed in Sect. 3.5 can serve as a routine quality-control metric for national capital accounts: a country whose $\hat{\rho}_2$ deviates markedly from unity warrants investigation before its wealth statistics are published.

International GDP comparability. Cross-country heterogeneity in $(\hat{\mu}, \beta)$ maps onto observable differences in investment composition. The one-size-fits-all depreciation schedules and zero-lag assumption used to construct PWT capital stocks therefore introduce a systematic comparability problem: countries with longer-gestation investment portfolios (Nordic economies, Republic of Korea) appear to have lower capital and higher TFP relative to countries with shorter-gestation portfolios (United States, United Kingdom). Tempo-correcting the capital stock before computing TFP would improve the comparability of cross-country productivity studies such as Inklaar and Timmer (2013).

6.5 Flow–stock reconciliation and Beyond-GDP

The Beyond-GDP programme has spent twenty years arguing that flow measures (GDP) should be replaced or augmented by stock measures (IWI, CWON, SEEA). The results here suggest a more constructive synthesis: flow and stock measures are *both* biased by ignored

hidden parameters, and they bias *in the same direction* once the parameters are made explicit. A reader who trusts CWON-produced capital as a gold standard for wealth accounting should also trust a PIM stock built with a time-varying $\mu(t)$ and a nonzero β , because those two series now agree to 1–2 % for most countries (Fig. 3). The practical route to Beyond-GDP is not to abandon the flow account but to audit it for tempo drift and for hidden β , just as the period total fertility rate was audited in the late 1990s.

Three implications follow for the Beyond-GDP conversation specifically. First, the argument that flow and stock accounts are irreconcilable — sometimes deployed to justify replacing GDP with a composite index — is not supported by the data once the accounts are audited on the same terms: once $\mu(t)$ and β are allowed, the two accounts agree to within the margin that separates any two reasonable national-statistics sources. Second, the composite-index direction (a single headline number that combines produced, human, and natural capital into one aggregate) is premature until the component-by-component reconciliation has been performed; adding categories before the existing categories are internally consistent only compounds the book-keeping problem. Third, the demographic-tempo literature evolved from Bongaarts and Feeney's (1998) original adjustment to a richer multi-parameter framework (Goldstein et al., 2003; Bongaarts and Sobotka, 2012) only after the single-parameter version was taken seriously and shown to be empirically productive. Capital-accounting tempo correction is at the same stage the fertility literature was in 1998: the one-parameter version here is not the last word, but it is a necessary first stop, and further parameters — asset-class heterogeneity in μ , country-specific β drift, interaction terms between μ and depreciation δ — are the natural next layer of refinement.

6.6 Extensions

The quantum-tempo decomposition is not specific to income statistics but to any stock-of-outcomes process whose flow is contaminated by drift in the timing distribution. A companion paper (in preparation) shows that the median lag from health expenditure to life-expectancy outcomes has been rising by roughly 0.15 years per calendar year since 2000 across the OECD, and that an analogous forgotten parameter explains an additional share of life-expectancy gaps. More broadly, any stock process whose timing structure drifts — the human-capital stock, the stock of accumulated medical R&D, the stock of climate adaptation capital — admits the same tempo-plus-forgotten-parameter correction. Cross-walking the capital-accounting machinery to

each of these domains is a programme, not a single paper; the present paper is the first stop on that programme.

6.7 Limitations

Three caveats apply. First, our identification of β against CWON is only as clean as CWON itself, and CWON combines national sources of heterogeneous quality — in particular, the treatment of land and sub-soil assets differs materially between Europe and the United States (Lange et al., 2018, Chap. 2), and our residual gap for Japan is at least partly attributable to land-price revaluations that CWON carries but our PIM construction does not. Second, the bootstrap CIs (Sect. 5.4) are wide for countries with short series or volatile investment, and we do not claim point identification for those countries; the framework provides interval estimates and a direction, and any country-specific policy conclusion should be cross-checked with national-accounts micro-data before being taken as settled. Third, the y_{price} sensitivity experiment (Sect. 5.3) treats the CWON deflator as a single country-level scalar; a more careful study would use sector-specific deflators, national land-price indices, and Tornqvist chained price indices for intangibles (Jorgenson et al., 2018), and is left to future work. A fourth caveat, perhaps the most important, is that the demographic-tempo analogy is suggestive but not exact: demographic stocks depreciate via well-measured mortality rates, whereas capital stocks depreciate via δ_t that is itself a derived estimate in PWT and is known to be imprecisely measured in transition economies (Inklaar and Timmer, 2013). If the true δ is itself drifting, some of what we attribute to $\mu(t)$ could instead be absorbed by a time-varying $\delta(t)$. Disentangling these two drifts requires auxiliary data on capacity utilisation and asset retirements that is not uniformly available across the 39 countries in our sample.

7 Conclusion

National income and wealth accounting has been asking the wrong question. The right question is not whether to use flows or stocks, but whether the parameters that link the two — the time-to-build of investment and the share of intangible capital — are estimated or imposed. When they are imposed ($\mu = 0$, $\beta = 0$) the accounting is silently biased, the Solow residual absorbs the error, and the flow and stock accounts drift apart. When μ is constructed from observable investment composition (M_{obs}), the measured capital stock changes by a median 4.3 %, TFP

shifts by 1.7 percentage points, and the implied labour share shifts by 1.7 percentage points — all without any free parameters. These are not forecasting improvements: they are measurement consequences that propagate to every macroeconomic quantity built on the national capital stock.

The scale of the measurement consequences deserves a final word of calibration. A 4.3 % change in the capital stock may sound modest, but it implies that the capital contribution to output — $\alpha \log K$ in every growth-accounting exercise since Solow (1957) — has been systematically biased for every country that has experienced a shift in investment composition toward long-gestation assets. For the Republic of Korea, the capital stock is overstated by 7.1 %, shifting TFP by 3.1 pp and the implied labour share by 3.1 pp; for Ireland the figures are 9.2 % and 4.6 pp. These magnitudes are comparable to the secular trends in labour shares that have generated a large literature (Karabarbounis and Neiman, 2014), suggesting that a non-trivial part of the measured decline in labour shares is an artefact of ignoring investment gestation lags.

Three practical recommendations follow from the results. First, any revision of national capital-stock estimates that treats μ as time-invariant should be treated as provisional; the observable M_{obs} construction demonstrates that the composition-driven tempo can be computed at negligible cost from existing OECD asset data. Second, the CWON and IWI programmes should consider publishing, alongside the point estimates, a set of joint-identified (μ, β) values implied by the flow and stock accounts together, so that users can see at a glance whether the two accounts are internally consistent or not. Third, methodologically, there is no principled reason for TFP growth to remain the residual of first resort. A post-tempo, post-intangible residual, computed after $\mu(t)$ and β have absorbed their share, is a more honest benchmark for productivity growth. That residual will be smaller than the Solow number, but it will also be more informative. Demography learned to live with a smaller "unexplained" component once the period-cohort bias was acknowledged; economic measurement is overdue the same adjustment.

Tables
